Web Search

Advances, Crawling & Link Analysis

Overview

A simple crawler

A real crawler

How hard can crawling be?

- •Web search engines must crawl their documents.
- •Getting the content of the documents is easier for many other IR systems.
 - •E.g., indexing all files on your hard disk: just do a recursive descent on your file system
- •Ok: for web IR, getting the content of the documents takes longer . . .
- •. . . because of latency.
- •But is that really a design/systems challenge?

Basic crawler operation

- •Initialize queue with URLs of known seed pages
- Repeat
 - ■Take URL from queue
 - •Fetch and parse page
 - Extract URLs from page
 - •Add URLs to queue
- •Fundamental assumption: The web is well linked.

Exercise: What's wrong with this crawler?

```
urlqueue := (some carefully selected set of seed urls)
             while urlqueue is not empty:
         myurl := urlqueue.getlastanddelete()
               mypage := myurl.fetch()
                fetchedurls.add(myurl)
           newurls := mypage.extracturls()
                 for myurl in newurls:
   if myurl not in fetchedurls and not in urlqueue:
                  urlqueue.add(myurl)
              addtoinvertedindex(mypage)
```

What's wrong with the simple crawler

- •Scale: we need to distribute.
- •We can't index everything: we need to subselect. How?
- •Duplicates: need to integrate duplicate detection
- Spam and spider traps: need to integrate spam detection
- Politeness: we need to be "nice" and space out all requests for a site over a longer period (hours, days)
- •Freshness: we need to recrawl periodically.
 - •Because of the size of the web, we can do frequent recrawls only for a small subset.
 - Again, subselection problem or prioritization

Magnitude of the crawling problem

- •To fetch 20,000,000,000 pages in one month . . .
- •. . . we need to fetch almost 8000 pages per second!
- •Actually: many more since many of the pages we attempt to crawl will be duplicates, unfetchable, spam etc.

What a crawler must do

Be polite

- Don't hit a site too often
- Only crawl pages you are allowed to crawl: robots.txt

Be robust

 Be immune to spider traps, duplicates, very large pages, very large websites, dynamic pages etc

Robots.txt

- •Protocol for giving crawlers ("robots") limited access to a website, originally from 1994
- **E**xamples:
 - User-agent: *

Disallow: /yoursite/temp/

•User-agent: searchengine

Disallow: /

•Important: cache the robots.txt file of each site we are crawling

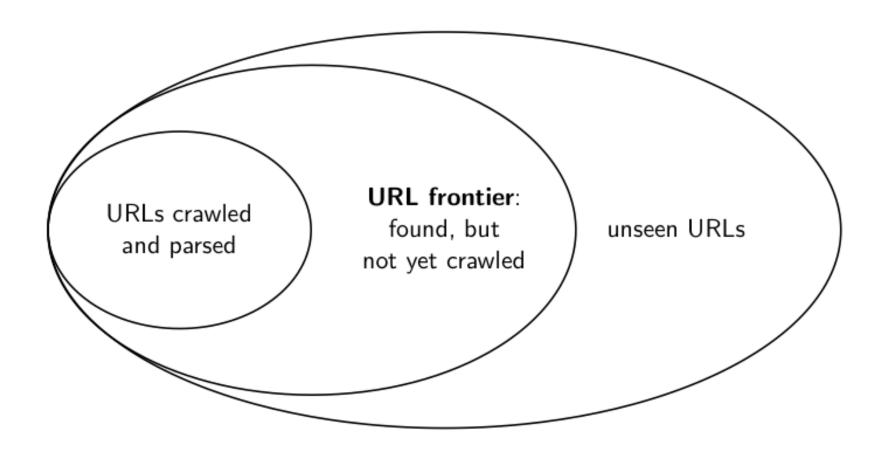

Example of a robots.txt (nih.gov)

```
User-agent: PicoSearch/1.0
  Disallow: /news/information/knight/
           Disallow: /nidcd/
Disallow: /news/research matters/secure/
        Disallow: /od/ocpl/wag/
             User-agent: *
  Disallow: /news/information/knight/
           Disallow: /nidcd/
Disallow: /news/research matters/secure/
        Disallow: /od/ocpl/wag/
            Disallow: /ddir/
         Disallow: /sdminutes/
```

What any crawler should do

- Be capable of distributed operation
- ■Be scalable: need to be able to increase crawl rate by adding more machines
- •Fetch pages of higher quality first
- Continuous operation: get fresh version of already crawled pages

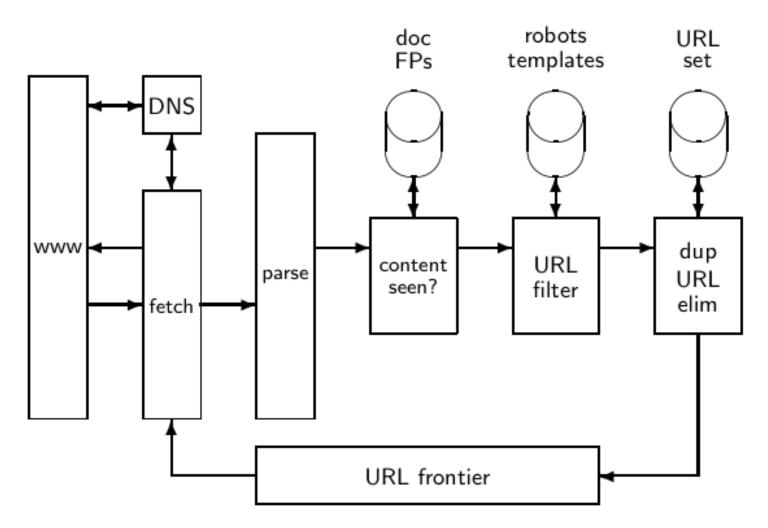

URL frontier

URL frontier

- •The URL frontier is the data structure that holds and manages URLs we've seen, but that have not been crawled yet.
 - •Can include multiple pages from the same host
 - •Must avoid trying to fetch them all at the same time
 - •Must keep all crawling threads busy

Basic crawl architecture

URL normalization

- •Some URLs extracted from a document are relative URLs.
 - •E.g., at http://mit.edu, we may have aboutsite.html
 - This is the same as: http://mit.edu/aboutsite.html
- •During parsing, we must normalize (expand) all relative URLs.

Content seen

- •For each page fetched: check if the content is already in the index
 - •Check this using document fingerprints or shingles
 - Skip documents whose content has already been indexed

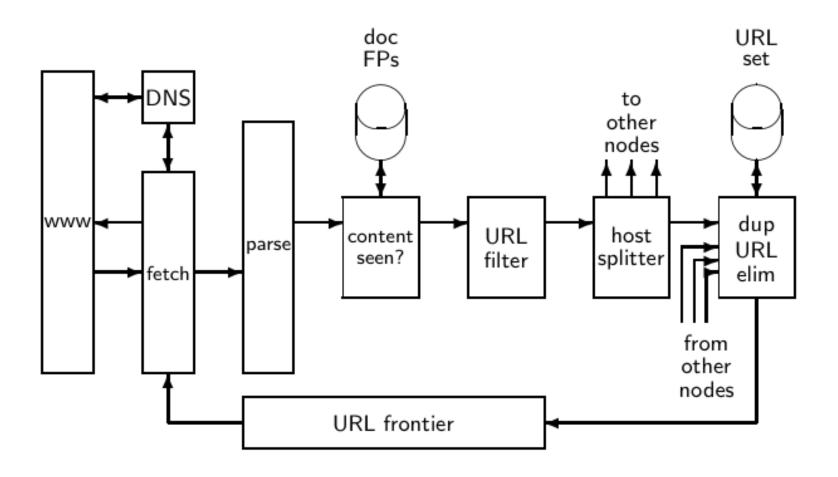

Distributing the crawler

- •Run multiple crawl threads, potentially at different nodes
 - Usually geographically distributed nodes
 - Partition hosts being crawled into nodes

Google data centers (wazfaring. com)

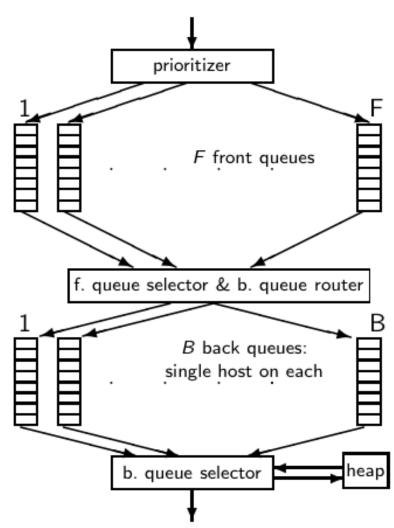

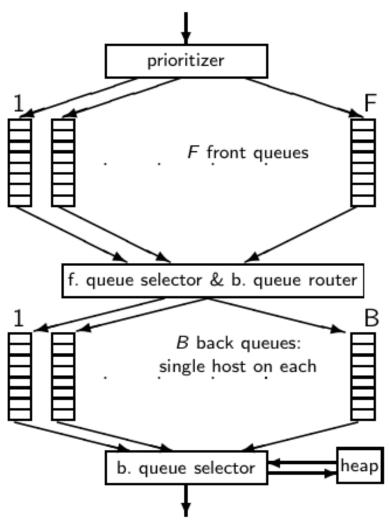

Distributed crawler

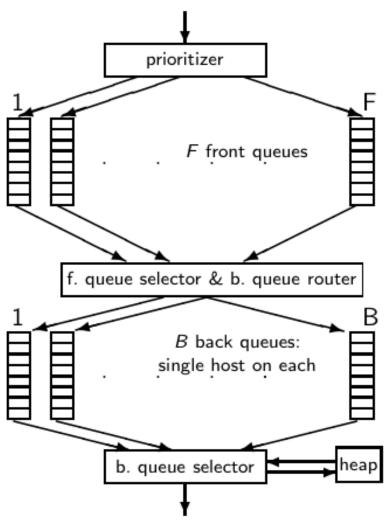

URL frontier: Two main considerations

- Politeness: Don't hit a web server too frequently
- •E.g., insert a time gap between successive requests to the same server
- •Freshness: Crawl some pages (e.g., news sites) more often than others
 - Not an easy problem: simple priority queue fails.

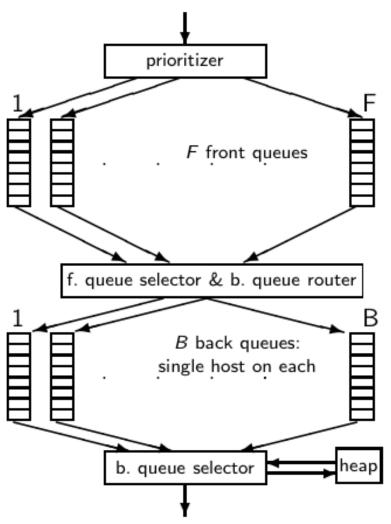

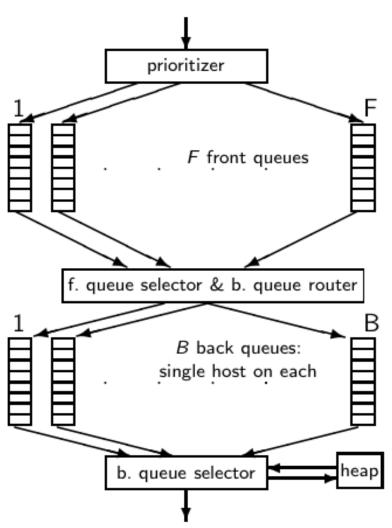

•URLs flow in from the top into the frontier.

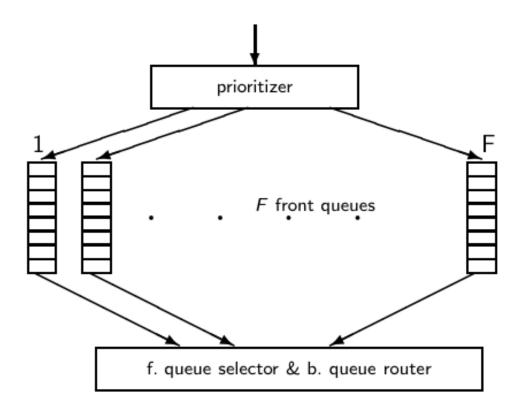

- •URLs flow in from the top into the frontier.
 - •Front queues manage prioritization.

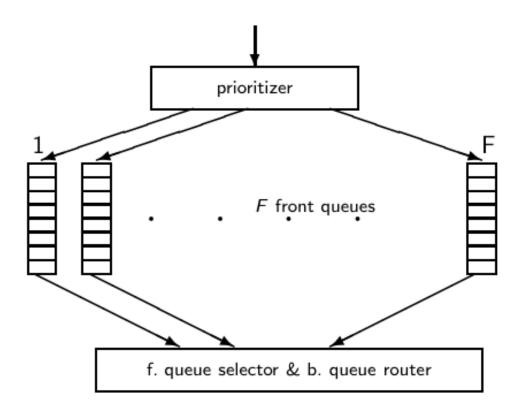

- •URLs flow in from the top into the frontier.
 - •Front queues manage prioritization.
- Back queues enforce politeness.

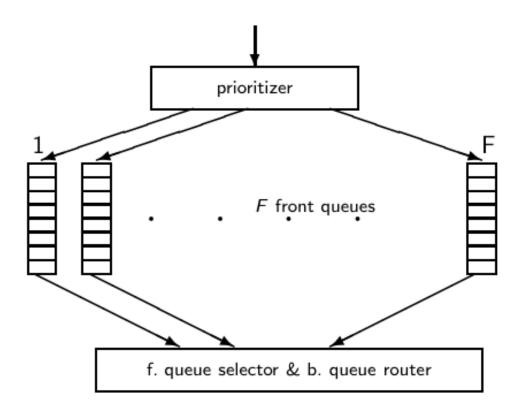

- •URLs flow in from the top into the frontier.
 - •Front queues manage prioritization.
- Back queues enforce politeness.
 - •Each queue is FIFO.

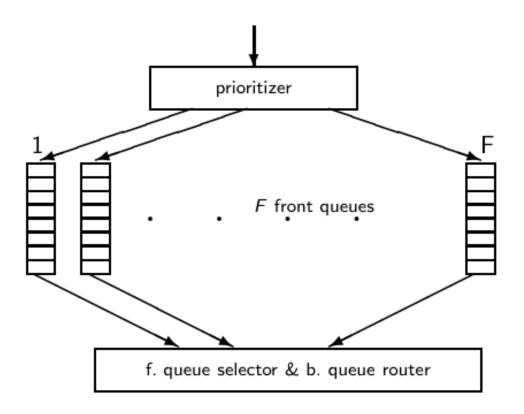

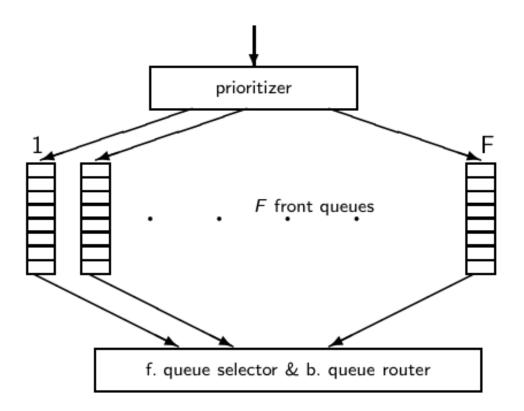

•Prioritizer assigns to URL an integer priority between 1 and *F*.

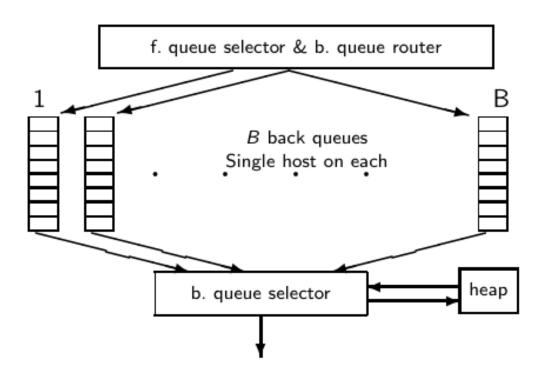

- •Prioritizer assigns to URL an integer priority between 1 and *F*.
 - Then appends URL to corresponding queue

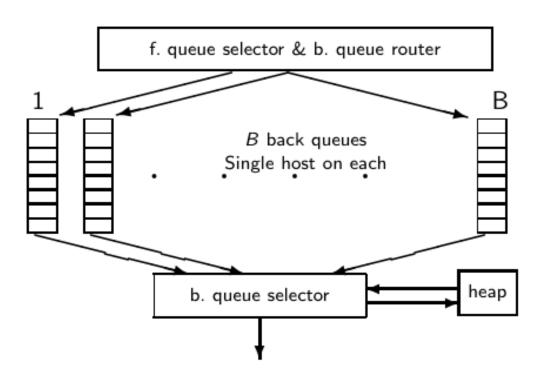

- •Prioritizer assigns to URL an integer priority between 1 and *F*.
 - Then appends URL to corresponding queue
- Heuristics for assigning priority: refresh rate, PageRank etc

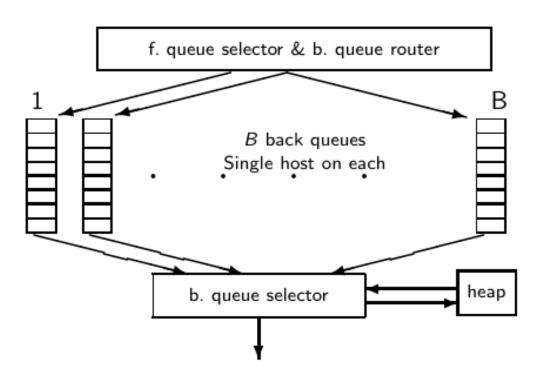

- Selection from front queues is initiated by back queues
- •Pick a front queue from which to select next URL: Round robin, randomly, or more sophisticated variant
 - But with a bias in favor of high-priority front queues

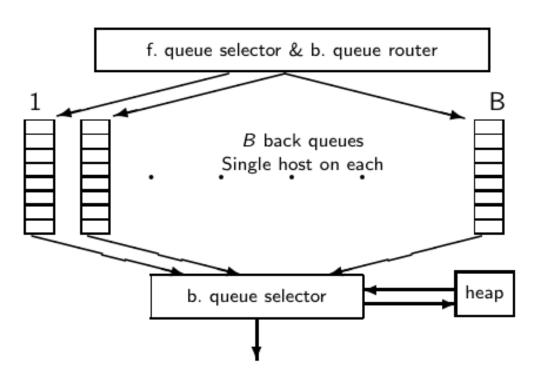

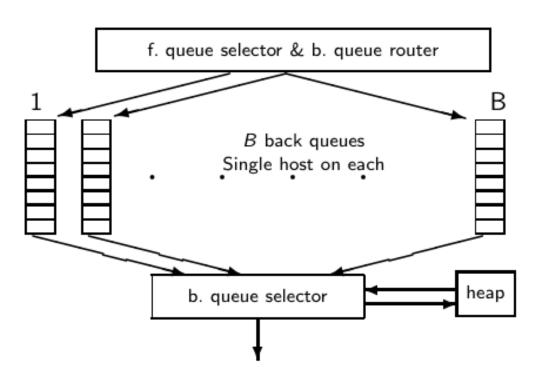

- Invariant 1. Each back queue is kept non-empty while the crawl is in progress.
 - •Invariant 2. Each back queue only contains URLs from a single host.
- •Maintain a table from hosts to back queues.

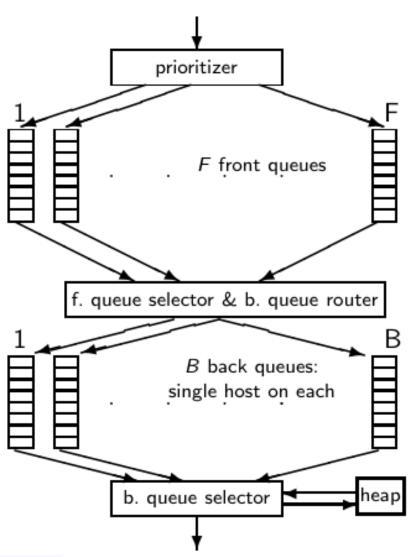

- In the heap:
- One entry for each back queue
- The entry is the earliest time t_e at which the host corresponding to the back queue can be hit again.
- The earliest time t_e is determined by (i) last access to that host (ii) time gap heuristic

- •How fetcher interacts with back queue:
- Repeat (i) extract current root qof the heap (q is a back queue)
- •and (ii) fetch URL u at head of $q \dots$
 - •. . . until we empty the q we get.
- •(i.e.: u was the last URL in q)

- •When we have emptied a back queue q:
- •Repeat (i) pull URLs *u* from front queues and (ii) add *u* to its corresponding back queue . . .
- •. . . until we get a *u* whose host does not have a back queue.
- •Then put *u* in *q* and create heap entry for it.

- •URLs flow in from the top into the frontier.
 - •Front queues manage prioritization.
 - Back queues enforce politeness.

Spider trap

- •Malicious server that generates an infinite sequence of linked pages
- •Sophisticated spider traps generate pages that are not easily identified as dynamic.

Resources

- •Chapter 20 of IIR
- Resources at http://ifnlp.org/ir
- Paper on Mercator by Heydon et al.
 - Robot exclusion standard

Meta-Search Engines

- Search engine that passes query to several other search engines and integrate results.
 - Submit queries to host sites.
 - Parse resulting HTML pages to extract search results.
 - Integrate multiple rankings into a "consensus" ranking.
 - Present integrated results to user.
- Examples:
 - Metacrawler
 - SavvySearch
 - Dogpile

HTML Structure & Feature Weighting

- Weight tokens under particular HTML tags more heavily (Semi-structured Data):
 - <TITLE> tokens (Google seems to like title matches)
 - -<H1>,<H2>... tokens
 - <META> keyword tokens
- Parse page into sections and weight tokens differently based on section: Multitier Indexing

Title, Abstract, Body,.....

• Links can also be a major factor (*Citations?*)

Bibliometrics: Citation Analysis

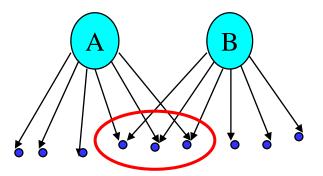

- Many standard documents include own bibliographies (or references), explicit citations to other previously published documents.
- Using citations as links, standard corpora can be viewed as a *graph*.
- The structure of this graph, independent of content, can provide interesting information about the similarity of documents and the structure of information.
- In Science/Academia this is the norm! Promotions

Impact Factor

- Developed by Garfield in 1972 to measure the importance (quality, influence) of scientific journals.
- Measure of how often papers in the journal are cited by other scientists.
- Computed and published annually by, e.g. the Institute for Scientific Information (ISI).
- The *Impact Factor* (IF) of a journal *J* in year *Y* is the average number of citations (from indexed documents published in year *Y*) to a paper published in *J* in year *Y*–1 or *Y*–2.
- Does not account for the quality of the citing article.

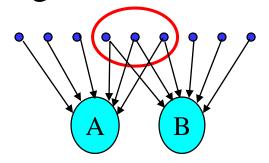

Bibliographic Coupling

- BC: A Measure of similarity of documents introduced by Kessler in 1963.
- The bibliographic coupling of two documents A and B is the number of documents cited by both A and B (documents based on same data are similar!)-overlap-.
- Size of the intersection of their bibliographies.
- Maybe want to normalize by size of bibliographies?

Co-Citation

- An alternate citation-based measure of similarity introduced by Small in 1973.
- Number of documents that cite both A and B. (Similar documents are cited in same articles!)
- Maybe want to normalize by total number of documents citing either *A* or *B*?

Citations vs. Links

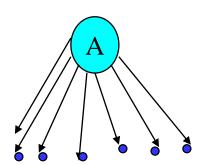

- Web links are a bit different than citations:
 - Many links are navigational.
 - Many pages with high in-degree are portals not content providers (not documents).
 - Not all links are endorsements.
 - Company websites don't point to their competitors.
 - Citations to relevant literature is <u>enforced</u> by peer-review. Not the case for web pages

Authorities

- Authorities are pages that are recognized as providing significant, trustworthy, and useful information on a topic (مرجع).
- *In-degree* (number of pointers to a page) is one simple measure of authority (6 here).
- However in-degree treats all links as equal.
- Should links from pages that are themselves authoritative count more?

Hubs

- *Hubs* are index pages that provide lots of useful links to relevant content pages (topic authorities). Large Out-Degree.
- Hub pages for IR are included in the course home page:

HITS (Hypertext Induced Topic Search)

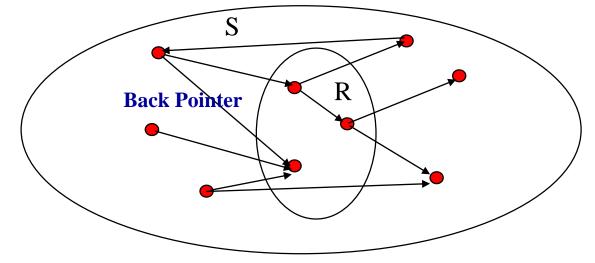

- Developed by Kleinberg in 1998.
- Attempts to determine hubs and authorities
 on a particular topic through analysis of a
 relevant subgraph of the web.
 Hubs Authorities
- Based on mutually recursive facts:
 - Hubs point to lots of authorities.
 - Authorities are pointed to by lots of hubs.
 - Hubs and Authorities together tend to form a bipartite graph:

HITS Algorithm

- Computes hubs and authorities for a particular topic specified by a normal query Q.
- First determines a set of relevant pages for the query called the *base* set *S*.
- Analyze the link structure of the web subgraph defined by S (pages linked with –to, from-S) to find authority and hub pages in this set.

Constructing a Base Subgraph

- For a specific query Q, let the set of documents returned by a standard search engine be called the *root* set R.
- Initialize S to R. Then expand as follows:
- Add to S all pages pointed to by any page in R.
- Add to S all pages that point to any page in R.

Base Limitations

- To limit computational expense:
 - Limit number of root pages to the top 200 pages retrieved for the query.
 - Limit number of "back-pointer" pages to a random set of at most 50 pages returned by a "reverse link" query.
- To eliminate purely navigational links:
 - Eliminate links between two pages on the same host.
- To eliminate "non-authority-conveying" links:
 - Allow only $m (m \approx 4-8)$ pages from a given host as pointers to any individual page.

Authorities and In-Degree

- Even within the base set S for a given query, the nodes with highest in-degree are not necessarily authorities (may just be generally popular pages like Yahoo or Amazon).
- True authority pages are pointed to by a number of hubs (i.e. pages that point to lots of authorities).

Iterative Algorithm

- Use an iterative algorithm to slowly converge on a mutually reinforcing set of hubs and authorities.
- Maintain for each page $p \in S$:
 - Authority score: a_p (vector \mathbf{a})
 - Hub score: h_p (vector h)
- Initialize all $a_p = h_p = 1$
- Maintain normalized scores:

$$\sum_{p \in S} (a_p)^2 = 1 \qquad \sum_{p \in S} (h_p)^2 = 1$$

HITS Update Rules

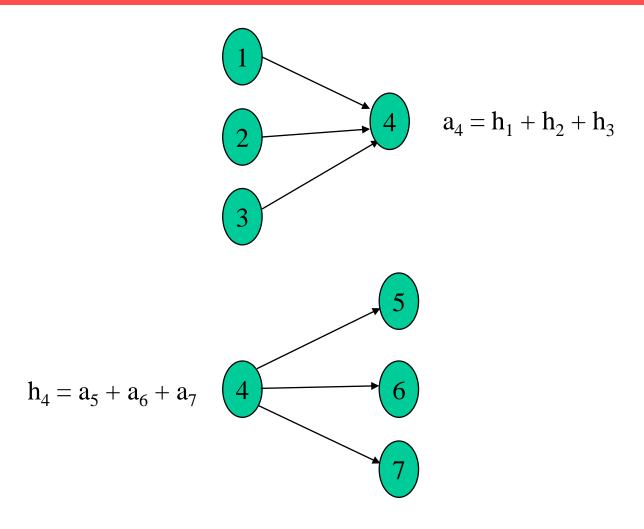

Authorities are pointed to by lots of good hubs:

$$a_p = \sum_{q:q \to p} h_q$$

Hubs point to lots of good authorities:

$$h_p = \sum_{q: p \to q} a_q$$

Illustrated Update Rules

HITS Iterative Algorithm

Initialize for all
$$p \in S$$
: $a_p = h_p = 1$
For $i = 1$ to k:

For all
$$p \in S:a_p = \sum_{q:q \to p} h_q$$
 (update auth. scores)

For all
$$p \in S$$
: $h_p = \sum_{q:p \to q} a_q$ (update hub scores)
For all $p \in S$: $a_p = a_p/c$ c :
$$\sum_{p \in S} (a_p/c)^2 = 1$$
 (normalize a)
For all $p \in S$: $h_p = h_p/c$ c :
$$\sum_{p \in S} (h_p/c)^2 = 1$$
 (normalize h)

Convergence

- Algorithm converges to a *fix-point* if iterated indefinitely.
- Define A to be the adjacency matrix for the subgraph defined by S.
 - $-A_{ij} = 1 \text{ for } i \in S, j \in S \text{ iff } i \rightarrow j$
- Authority vector, \boldsymbol{a} , converges to the principal eigenvector of A^TA
- Hub vector, \mathbf{h} , converges to the principal eigenvector of AA^T
- In practice, 20 iterations produces fairly stable results.

Results

- Authorities for query: "Java"
 - java.sun.com
 - comp.lang.java FAQ
- Authorities for query "search engine"
 - Yahoo.com
 - Excite.com
 - Lycos.com
 - Altavista.com
- Authorities for query "Gates"
 - Microsoft.com
 - roadahead.com

Result Comments

- In most cases, the final authorities were not in the initial root set generated using Altavista.
- Authorities were brought in from linked and reverse-linked pages and then HITS computed their high authority score.

Finding Similar Pages Using Link Structure

- Given a page, P, let R (the root set) be t (e.g. 200) pages that point to P.
- Grow a base set S from R.
- Run HITS on S.
- Return the best authorities in *S* as the best similar-pages for *P*.
- Finds authorities in the "link neighbor-hood" of *P*.

Similar Page Results

- Given "honda.com"
 - toyota.com
 - ford.com
 - bmwusa.com
 - saturncars.com
 - nissanmotors.com
 - audi.com
 - volvocars.com

HITS for Clustering

- An ambiguous query can result in the principal eigenvector only covering one of the possible meanings.
- Non-principal eigenvectors may contain hubs & authorities for other meanings.
- Example: "jaguar":
 - Atari video game (principal eigenvector)
 - NFL Football team (2nd non-princ. eigenvector)
 - Automobile (3rd non-princ. eigenvector)

PageRank

- Alternative link-analysis method used by Google (Brin & Page, 1998).
- Does not attempt to capture the distinction between hubs and authorities.
- Ranks pages just by authority.
- Applied to the entire web rather than a local neighborhood of pages surrounding the results of a query.

Initial PageRank Idea

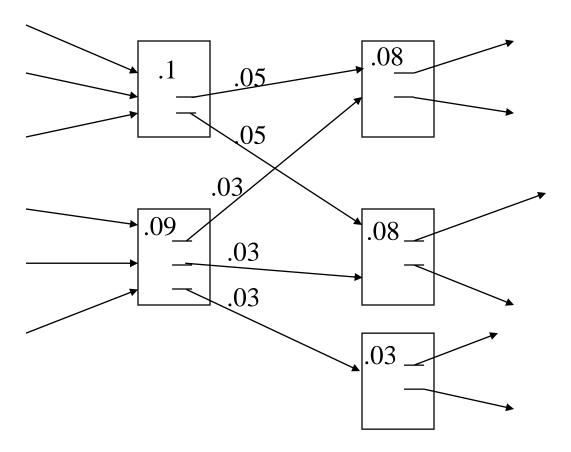

- Just measuring in-degree (citation count) doesn't account for the authority of the source of a link.
- Initial page rank equation for page *p*:

$$R(p) = c \sum_{q:q \to p} \frac{R(q)}{N_q}$$

- $-N_q$ is the total number of out-links from page q.
- A page, q, "gives" an equal fraction of its authority to all the pages it points to (e.g. p).
- c is a normalizing constant set so that the rank of all pages always sums to 1.

Initial PageRank Idea (cont.)

Can view it as a process of PageRank
 "flowing" from pages to the pages they cite.

Initial Algorithm

• Iterate rank-flowing process until convergence: Let S be the total set of pages.

Initialize $\forall p \in S: R(p) = 1/|S|$

Until ranks do not change (much) (convergence)

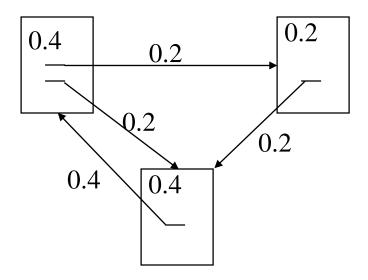

For each $p \in S$:

$$R'(p) = \sum_{q:q \to p} \frac{R(q)}{N_q}$$

$$c = 1/\sum_{p \in S} R'(p)$$

For each $p \in S$: R(p) = cR'(p) (normalize)

Sample Stable Fixpoint

Linear Algebra Version

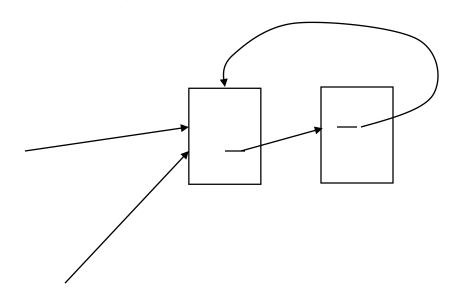

- Treat **R** as a vector over web pages.
- Let A be a 2-d matrix over pages where

$$-\mathbf{A}_{vu} = 1/N_u \text{ if } u \rightarrow v \text{ else } \mathbf{A}_{vu} = 0$$

- Then $\mathbf{R} = c\mathbf{A}\mathbf{R}$
- R converges to the principal eigenvector of A.

Problem with Initial Idea

 A group of pages that only point to themselves but are pointed to by other pages act as a "rank sink" and absorb all the rank in the system.

Rank flows into cycle and can't get out

Rank Source

• Introduce a "rank source" E that continually replenishes the rank of each page, p, by a fixed amount E(p).

$$R(p) = c \left(\sum_{q:q \to p} \frac{R(q)}{N_q} + E(p) \right)$$

PageRank Algorithm

Let S be the total set of pages.

Let $\forall p \in S: E(p) = \alpha/|S|$ (for some $0 < \alpha < 1$, e.g. 0.15)

Initialize $\forall p \in S: R(p) = 1/|S|$

Until ranks do not change (much) (convergence)

For each $p \in S$:

$$R'(p) = \left[(1 - \alpha) \sum_{q:q \to p} \frac{R(q)}{N_q} \right] + E(p)$$

$$c = 1/\sum_{p \in S} R'(p)$$

For each $p \in S$: R(p) = cR'(p) (normalize)

Linear Algebra Version

- $\mathbf{R} = \mathbf{c}(\mathbf{A}\mathbf{R} + \mathbf{E})$
- Since $\|\mathbf{R}\|_1 = 1$: $\mathbf{R} = c(\mathbf{A} + \mathbf{E} \times \mathbf{1})\mathbf{R}$
 - Where 1 is the vector consisting of all 1's.
- So **R** is an eigenvector of $(\mathbf{A} + \mathbf{E} \times \mathbf{1})$

Random Surfer Model

- PageRank can be seen as modeling a "random surfer" that starts on a random page and then at each point:
 - With probability E(p) randomly jumps to page p.
 - Otherwise, randomly follows a link on the current page.
- R(p) models the probability that this random surfer will be on page p at any given time.
- "E jumps" are needed to prevent the random surfer from getting "trapped" in web sinks with no outgoing links.

Speed of Convergence

- Early experiments on Google used 322 million links.
- PageRank algorithm converged (within small tolerance) in about 52 iterations.
- Number of iterations required for convergence is empirically O(log *n*) (where *n* is the number of links).
- Therefore calculation is quite efficient.

Simple Title Search with PageRank

- Use simple Boolean search to search webpage titles and rank the retrieved pages by their PageRank.
- Sample search for "university":
 - Altavista returned a random set of pages with "university" in the title (seemed to prefer short URLs).
 - Primitive Google returned the home pages of top universities.

Google Ranking

- Complete Google ranking includes (based on university publications prior to commercialization).
 - Vector-space similarity component.
 - Keyword proximity component.
 - HTML-tag weight component (e.g. title preference).
 - PageRank component.
- Details of current commercial ranking functions are trade secrets.

Personalized PageRank

- PageRank can be biased (personalized) by changing E to a non-uniform distribution.
- Restrict "random jumps" to a set of specified relevant pages.
- For example, let E(p) = 0 except for one's own home page, for which $E(p) = \alpha$
- This results in a bias towards pages that are closer in the web graph to your own homepage.

Google PageRank-Biased Spidering

- Use PageRank to direct (focus) a spider on "important" pages.
- Compute page-rank using the current set of crawled pages.
- Order the spider's search queue based on current estimated PageRank.

Link Analysis Conclusions

- Link analysis uses information about the structure of the web graph to aid search.
- It is one of the major innovations in web search.
- It was one of the primary reasons for Google's initial success.
